Early diagnosis improves survival in colorectal cancer

How do patients present?

COLORECTAL CANCER IS THE SECOND MOST COMMON CAUSE OF DEATH FROM CANCER IN the UK.1 In 2009, there were 41,142 new cases of colorectal cancer, 22,711 (55%) in men and 18,431 (45%) in women in the UK.2

Around two-thirds of all bowel cancers originate in the colon, the other third occur in the rectum including the anus.

The UK has one of the lowest survival rates for colorectal cancer in Europe. Collaborative work from cancer registries across Europe has indicated that early symptom recognition and early diagnosis are important factors in improving survival.3

Common alarm symptoms for colorectal cancer include:
• rectal bleeding
• change in bowel habit (with a tendency toward diarrhoea)
• iron deficient anaemia.

Abdominal mass, weight loss, nausea and vomiting, anorexia and abdominal swelling are less common presenting symptoms. Patients with lesions in the rectum or sigmoid colon commonly report rectal bleeding and change in bowel habit4 whereas those with proximal tumours have more subtle symptoms which can be difficult to differentiate from benign disease.5,6

What are the risk factors?

RISK FACTORS
Colorectal cancer has a male predominance and is strongly associated with age, 80% of new cases occur in patients aged over 60.7

Lifestyle factors are important in colorectal cancer. Obesity8 and limited exercise9 are strong risk factors. Diets low in fruit and vegetables10 and fibre11 and high in red meat12 have also been associated with an increased risk. Family history is a common reason for patients to seek advice on screening for bowel cancer.

What are the treatment options?

Patients with one first-degree relative under 45 or two first-degree relatives of any age have an approximate lifetime risk of developing colorectal cancer of 16-25%, in men, and 10-15%, in women. Having one first-degree relative who developed the disease after the age of 65 barely increases lifetime risk.13

Rarer genetic conditions such as familial adenomatous polyposis and hereditary non-polyposis colorectal cancer are associated with < 5% of cases of bowel cancer but are often responsible for the development of colorectal cancer at a younger age.2

Patients with a significant family history or known genetic predisposition should be referred to specialist clinics for further evaluation.

Patients with ulcerative colitis and Crohn’s colitis have an increased lifetime risk of colorectal cancer. This risk is dependent on the extent, severity and duration of the colitis, and these

CT colonography is a technique which offers a less invasive alternative to colonoscopy. It is particularly useful in patients with major comorbidity or contraindications to colonoscopy to establish a diagnosis of colorectal cancer. In patients who have undergone surgery for colorectal cancer, CT has the potential to screen for both metastases as well as further colonic lesions. However, CT colonography is dependent on local radiological expertise and its exact role in colorectal cancer screening and surveillance still needs to be fully evaluated.

Magnetic resonance imaging
Magnetic resonance imaging (MRI) is a particularly valuable investigation in rectal cancer. It is used preoperatively to stage the tumour and predict risk of recurrence. If the MRI scan shows the tumour is amenable to local excision or if MRI is contraindicated, patients should be considered for endorectal ultrasound.

REFERRAL
In 2004, NICE outlined high risk criteria, see table 1, above, to help stratify referral patterns for suspected colorectal cancer. Although it emphasised that new and persistent symptoms require prompt investigation it did note that in more equivocal cases ‘treat, watch and wait’ is also an acceptable approach.10 Patients meeting the NICE criteria for urgent referral should be referred via the two week wait pathway to the local colorectal department for prompt assessment to exclude colorectal cancer. Recent research has explored combining common early symptoms to develop an algorithm to give an absolute risk of colorectal cancer and prompt early referral for investigation. The QCanter risk score has been incorporated in certain GP record systems to highlight at-risk patients. However, diagnostic pathways and cost-effectiveness modelling for this algorithm are still required before this approach can be more widely adopted in primary care.21

Table 1

<table>
<thead>
<tr>
<th>NICE criteria for urgent referral</th>
<th>Age threshold</th>
</tr>
</thead>
<tbody>
<tr>
<td>Rectal bleeding with a change in bowel habit to looser stools and/or increasing frequency of defecation, persistent for six weeks</td>
<td>All ages</td>
</tr>
<tr>
<td>A definite palpable right-sided abdominal mass</td>
<td>All ages</td>
</tr>
<tr>
<td>A definite palpable rectal (not pelvic) mass</td>
<td>All ages</td>
</tr>
<tr>
<td>Rectal bleeding persistently without anal symptoms (soreness, discomfort, itching, lumps, prolapse)</td>
<td>Over 60 years</td>
</tr>
<tr>
<td>Change of bowel habit to looser stools and/or increased frequency of defecation, without rectal bleeding and persistent for six weeks</td>
<td>Over 60 years</td>
</tr>
<tr>
<td>Iron deficiency anaemia without an obvious cause (Hb &lt; 11g/dl in men and &lt;10g/dl in postmenopausal women)</td>
<td>No age criterion</td>
</tr>

Factors inform the guidelines on the colonoscopy surveillance of patients with inflammatory bowel disease.14

SCREENING
The NHS Bowel Cancer Screening Programme (BCSP) was introduced in England in 2006 after several successful pilot studies.15 The programme offers screening to all patients between the ages of 60 and 69 and is in the process of being extended to patients aged 70-74.16 The respective screening age ranges for Wales, Scotland and N. Ireland are 60-74, 50-74 and 60-71. Presently patients are screened with a faecal occult blood test (FOBT) which they complete at home and return by post. Patients with positive tests are then offered further investigation, typically colonoscopy.

Following a multicentred randomised controlled trial which showed that once only flexible sigmoidoscopy between the ages of 55 and 64 reduced colorectal cancer mortality by 43%,17 the NHS BCSP plans to introduce flexible sigmoidoscopy to the current screening programme as a one-off test for both men and women at age 55. It is expected to be introduced in the next few years. Patients in colorectal cancer surveillance programmes because of previous polyps or colitis should only be followed up as long as they are medically fit to undergo treatment. The interval for surveillance should follow British Society of Gastroenterology guidelines.14,18

Patients outside the screening or surveillance programmes who present with alarm symptoms of colorectal cancer should be referred urgently under the two week wait pathway for further investigation. Patients typically need to undergo one or more investigation(s) to confirm or exclude a diagnosis of colorectal cancer.

INVESTIGATIONS
Faecal occult blood test
The FOBT is a cheap, non-invasive method for detecting blood in the stool. Several randomised controlled trials have shown that population screening with FOBT every two years has the potential to reduce colorectal cancer mortality by 15-18%.19,20,21 The NHS BCSP uses an unhydrated FOBT so pre-test work up restrictions are not necessary.

Carcinoembryonic antigen
Carcinoembryonic antigen (CEA) is a complex glycoprotein produced in about 90% of colorectal cancer cases.23 However, it is elevated in a number of other malignant and benign conditions thus it lacks sensitivity and specificity as a screening tool.24

Following surgery for colorectal cancer CEA has been shown to be a sensitive predictor of recurrence25,26 and therefore it is recommended that patients should have a CEA test at least every six months for the first three years after surgery.

Colonoscopy
The sensitivity of colonoscopy for detecting abnormalities is > 90% and hence it is the gold standard test for evaluating the large bowel.27 It allows the bowel to be visualised and biopsies to be taken to gain histological confirmation of the diagnosis. Colonoscopy should be offered to patients with a suspected colonic lesion without major comorbidity or contraindications.

Complications following a colonoscopy are rare but include significant bleeding (about 1 in 400) and perforation of the bowel (about 1 in 2,500).28 On discharge after the test, patients will be counselled about what to look out for and will be given advice on what to do if any of these complications arise.

Flexible sigmoidoscopy
Flexible sigmoidoscopy is a limited investigation visualising the left side of the colon where approximately 60% of colorectal cancers develop.29 Patients with significant comorbidities it is often combined with a barium enema or CT scan to provide a less invasive assessment of the bowel.

Computed tomography
Once a diagnosis of colorectal cancer has been confirmed, the extent of disease is evaluated by a computerised tomography (CT) scan of the chest, abdomen and pelvis.

TREATMENT
All patients with colorectal cancer should have their case discussed, and a treatment plan decided, at a dedicated multidisciplinary team (MDT) meeting. Patients should then be invited to attend a specialist clinic where they are given written and oral information on the treatment options available. This information should include the potential benefits and risks of these treatments including the effect on bowel function and the prognosis with no treatment.
The treatment of colorectal cancer depends on the site and stage of the disease. The stage of the tumour reflects the depth of tumour invasion and is closely linked to survival, see table 2, above.

**Stage I**
Although stage I tumours were previously rare the NHS BCSP is detecting increasing numbers, however, the optimum management of these very early tumours is unclear. At present although some consensus can be reached on which pathological risk factors lead to poorer outcomes, there is no evidence about how these factors might be used to guide subsequent clinical management, particularly if resection margins are clear. Some clarity is expected over the coming years from following up this patient group closely.

**Stages II and III**
Patients should be offered surgical resection of their tumour. This can be performed by an open or laparoscopic procedure depending on local expertise, suitability of the patient for a laparoscopic technique and following discussion with the patient about the potential risks and benefits of the two procedures.

Before surgery all patients should be advised on the likelihood of having a stoma and should be counselled and educated about stoma management by a dedicated stoma nurse.

Adjuvant chemotherapy should be considered after surgery in all patients with colorectal cancer greater than stage II. Specifically in stage III disease, capecitabine can be used as monotherapy or oxaliplatin in combination with 5-fluorouracil and folic acid. Stage IV

If the staging CT reveals metastatic disease the priority of treatment should be to control the patient’s symptoms.

If spread is confined to the liver and the patient has no contraindications to further intervention, the case should be discussed at a hepatobiliary MDT to decide if the liver lesions are resectable. Typically patients undergo resection of their colonic primary with adjuvant chemotherapy followed by subsequent resection of their liver metastases once they have recovered.

Detailed imaging of other sites for suspected metastasis should only be performed as symptoms arise.

If intracranial disease is suspected, patients should be offered a contrast-enhanced MRI brain scan.

Radical surgery is occasionally possible for extra-hepatic metastases but will require discussion at a site-specific MDT. Positron emission tomography (PET-CT) may be useful in evaluating these lesions. If imaging remains equivocal for extrahepatic disease patients should be kept under regular clinic review with interval imaging.

Chemotherapy should be offered for advanced and metastatic colorectal cancer. One of the following sequences of chemotherapy are offered unless there is a contraindication or the patient has been recruited to a trial:

- **FOLFOX** (folinic acid plus fluorouracil plus oxaliplatin) as first-line treatment then single agent irinotecan as second-line treatment
- **FOLFOX** as first-line treatment then **FOLFIRI** (folinic acid plus fluorouracil plus irinotecan) as second-line treatment
- The exact role and safety of colonic stents continues to be investigated. Current recommendations are that their insertion should be attempted urgently and no longer than 24 hours after patients present with colonic obstruction.

**RECTAL CANCER**
Rectal tumours which are determined to have a low risk of recurrence based on MRI findings can be managed by transanal excision or radical surgery. Moderate-risk tumours with extramural or lymphovascular invasion, should probably have additional treatment before definitive surgery. Typically this is a short course of preoperative radiotherapy or chemoradiotherapy to enable tumour shrinkage.

Although radiotherapy reduces the risk of recurrence, it carries a significant risk of morbidity, particularly to sphincter function which should be highlighted to the patient before treatment.

In operable patients with a high risk of recurrence, preoperative chemoradiotherapy should be performed before surgery. Preoperative chemoradiotherapy should not be offered solely to facilitate sphincter-sparing surgery. Adjuvant chemotherapy can also be considered in rectal cancers of stage II and above.

**FOLLOW-UP**
After curative resection patients should be followed up in a colorectal clinic initially every four to six weeks. They should be offered regular surveillance for recurrence and metastatic disease with a minimum of two CT scans of their chest, abdomen, and pelvis in the first three years and regular CEA tests.

At one year after treatment patients should be offered a surveillance colonoscopy. If this investigation is normal further colonoscopic follow-up.
Colorectal cancer is the second most common cause of death from cancer in the UK. In 2009, there were 41,142 new cases registered. The UK has one of the lowest survival rates for colorectal cancer in Europe. Common alarm symptoms include rectal bleeding, change in bowel habit and iron deficiency anaemia. Abdominal mass, weight loss, nausea and vomiting, anorexia and abdominal swelling are less common presenting symptoms. Patients meeting the NICE criteria for urgent referral should be referred via the two week wait pathway to the local colorectal department for prompt assessment to exclude colorectal cancer.

Colorectal cancer has a male predominance and is strongly associated with age, 80% of new cases occur in patients aged over 60. Obesity and limited exercise are strong risk factors. Diets low in fruit and vegetables and fibre and high in red meat have also been associated with an increased risk. Patients with one first-degree relative under 45 or two first-degree relatives of any age have an approximate lifetime risk of developing colorectal cancer of 16–25% in men and 10–15% in women. Having one first-degree relative who developed the disease after the age of 65 barely increases lifetime risk. Patients with ulcerative colitis and Crohn’s colitis also have an increased lifetime risk of colorectal cancer.

In the NHS Bowel Cancer Screening Programme, patients are screened with a faecal occult blood test (FOBT) which they complete at home and return by post. Patients with positive tests are then offered further investigation, typically colonoscopy. The sensitivity of colonoscopy for detecting abnormalities is > 90% and hence it is the gold standard test for evaluating the large bowel. Once a diagnosis of colorectal cancer has been confirmed, the extent of disease is evaluated by a CT scan of the chest, abdomen and pelvis.

The treatment of colorectal cancer depends on the site and stage of the disease. The stage of the tumour reflects the depth of tumour invasion and is closely linked to the depth of tumour invasion and is closely linked to survival. Currently it is recommended in stage I disease that if the histology reveals that the tumour involves, or is within 1mm of, the resection margin, further treatment should be considered. This could be surgical resection or endoscopic surveillance with or without further polypectomy. With stage II and III disease patients should be offered surgical resection of their tumour. If the staging CT reveals metastatic disease the priority of treatment should be to control patient symptoms.

After curative resection patients should be followed up in a colorectal clinic initially every four to six weeks. They should be offered regular surveillance for recurrence and metastatic disease with a minimum of two CT scans of their chest, abdomen, and pelvis in the first three years and regular CEA tests. Prompt reinvestigation of the patient should be commenced if there is any clinical, radiological or biochemical suspicion of recurrent disease.

is not required for a further five years. Thereafter surveillance is arranged on an individual basis, reflecting personal risk factors and emergent symptoms. The timing of surveillance for patients with subsequent adenomas should be determined by the number and type of adenomas. Prompt reinvestigation of the patient should be commenced if there is any clinical, radiological or biochemical suspicion of recurrent disease. Follow-up should be ceased following discussion between the patient and the healthcare professional regarding the necessity and benefits of further investigations and treatments.

CONCLUSION
Colorectal cancer is a common malignancy associated with significant mortality. Prognosis can be much improved if the disease is diagnosed at an early stage. GPs play an important role in recognising symptoms and supporting patients through the investigation and ongoing management of their disease. They may be called upon to act as an advocate for their patient in the facilitation of necessary investigations. During and after treatment patients may have significant ongoing morbidity which can be life changing. Patients often need support during this period along with advice about symptom management and ongoing medical or palliative care. GPs are ideally placed to provide this advice in addition to psychosocial support for both patients and their relatives.
