Managing urticaria in primary care

Managing urticaria in primary care

DR MICHAEL J. TIDMAN

Consultant Dermatologist,
Department of Dermatology, Royal Infirmary of Edinburgh, Edinburgh, UK

URTICARIA (DERIVED FROM URTICA, LATIN FOR NETTLE) IS A COMMON CONDITION THAT CAN affect all age groups. It is often referred to as hives or nettle rash. Urticaria is characterised by transient wheals that consist of a swollen palpable centre often surrounded by an erythematous flare, see figure 1, above, and figure 2, p26. The lesions are associated with itching or, less commonly, a burning sensation. Typically, individual wheals disappear rapidly (usually within 1 to 24 hours) leaving normal skin.

In 50% of cases, wheals may be accompanied by angioedema, a more deep-seated, flesh-coloured or erythematous swelling of the skin or mucous membrane (particularly eyelids, lips, tongue and upper aerodigestive tract). This may last considerably longer than 24 hours. Angioedema is not usually itchy but may be painful, and may occasionally occur without wheals, for instance in C1 inhibitor deficiency or as an adverse effect of ACE inhibitor therapy.

Urticaria is not usually accompanied by systemic symptoms.

A multinational guideline has been published recently covering the definition, classification and diagnosis of urticaria, and giving evidence-based therapeutic options, many of which are appropriate to primary care practitioners.¹

Urticaria is classified as acute when it resolves within six weeks and as chronic when its duration exceeds six weeks. Chronic urticaria is now sub-classified into chronic spontaneous urticaria (CSU) and chronic inducible urticaria (CIU). The latter subtype includes variants that were known as the physical urticarias, see box 1, p26.¹ CSU and CIU may co-exist.

Urticarial vasculitis and urticaria pigmentosa are not classified as urticaria because of their distinctly different pathomechanisms.¹ Autoinflammatory syndromes can

What are the potential complications?

‘Urticaria is not usually accompanied by systemic symptoms’

What are the management options?

Which patients should be referred?
Angioedema of the tongue and vocal cords can cause acute obstruction of the upper airway requiring emergency measures. Patients with urticaria should be warned about this, albeit unlikely, consequence.

Very occasionally, urticaria may progress to anaphylaxis, and conversely, urticaria may be a feature of anaphylactic reactions.

Acute spontaneous urticaria is common in infants and young children, particularly in atopic individuals and, more frequently than in older children and adults, may be associated with a sensitisation to foods such as milk, eggs and peanuts. In this young age group, food-induced urticaria may be a harbinger of anaphylaxis.

An individual with cold urticaria is at risk of massive histamine release into the circulation if immersed in cold water, sufficient to cause hypotension and fainting with potentially fatal consequences.

‘Very occasionally urticaria may progress to anaphylaxis, and conversely, urticaria may be a feature of anaphylactic reactions’

DIAGNOSIS

A history from the patient of an itchy rash, the individual components of which last a matter of hours is enough to seal a diagnosis of urticaria, especially if complemented by the presence of wheals on examination or in a photograph taken by the patient.

The persistence of wheals for more than 24-36 hours should prompt consideration of a vasculitic aetiology (urticarial vasculitis), requiring a diagnostic skin biopsy and appropriate investigation.

CSU may co-exist with one of the physical urticarias. Patients should be asked if they are able to induce wheals to appear.

If the history is suggestive, appropriate testing (when no antihistamine is being taken by the patient) would include:

- Histamine-releasing autoantibodies directed against either IgE or the high affinity mast cell receptor for IgE
- Possibly certain bacterial (such as Helicobacter pylori), viral, parasitic and fungal infections, although the role of infection in urticaria remains to be precisely clarified
- Drugs
- Various physical stimuli

Patients with urticaria frequently present to primary care in the belief that their rash is the result of allergy. However, IgE-mediated food allergy is rarely the cause of CSU in patients with the daily appearance of urticarial lesions, although it should be considered in CSU patients with intermittent symptoms.

Pseudoallergy (non-IgE-mediated hypersensitivity reactions) to NSAIDs and food ingredients (such as salicylates, additives, preservatives, dyes and antioxidants) may both elicit and aggravate CSU and may be of relevance in CSU with daily symptoms.

POTENTIAL COMPLICATIONS

Chronic urticaria frequently has a significant detrimental effect on quality of life, associated with sleep disturbance, depression and embarrassment, and may also affect performance at work and school.

Wheals induced by gentle trauma to the skin in symptomatic dermographism

Pharmacological treatment
The symptoms of urticaria are predominantly mediated by the interaction of histamine, released by mast cells, and H1 receptors located on endothelial cells and sensory nerves. Thus H1 antihistamine therapy is recommended as first-line symptomatic treatment for urticaria. The modern second-generation H1 antihistamines are preferred over first-generation H1 antihistamines as they are relatively non-sedating and have a good safety profile. However, only cetirizine, levocetirizine, loratadine, desloratadine, fexofenadine, rupatadine and bilastine have been adequately studied in CSU. In CSU they should be taken

INVESTIGATIONS
Routine investigations are not considered necessary in acute urticaria.1,2 For patients with CSU a differential full blood count and inflammatory markers (ESR or CRP)

Management
General measures
An information leaflet, such as that produced by the British Association of Dermatologists (www.bad.org.uk), should be given to patients or their carers. It is important to stress that the cause of the urticaria may not be found.2 Consideration should be given to possible trigger factors such as drugs, physical stimuli, inflammation, infection and infestation.

If possible, NSAIDs and opiates should be avoided as they may exacerbate a tendency to urticaria through a non-allergic mechanism. IgE-mediated food allergy is rarely the underlying trigger for CSU, but in those cases where sensitisation to a food has been demonstrated (by the presence of a specific IgE or positive skin prick testing) and shown to be clinically relevant, strict avoidance should be advised. A trial of a low pseudoallergen diet is now recommended (for a minimum of three weeks to establish its effectiveness, and thereafter for at least three to six months) in cases of CSU with daily or virtually daily symptoms (www.ecarf.org/).1,3

Topical therapy (1% menthol in aqueous cream and calamine lotion) can be soothing for the pruritus of urticaria, and although the short-term use of topical corticosteroids can be helpful their routine use is not recommended.2 Topical antihistamines may result in sensitisation and contact dermatitis, and thus should be avoided in urticaria.

patient) can be undertaken in the surgery:

Dermographism can be excluded by firm stroking of the skin with a blunt instrument, such as a ball pen, see figure 3, above

Cholinergic urticaria may be precipitated by exercise appropriate to the patient’s general health

Cold urticaria can be easily confirmed by the development of an urticated plaque at the site of application of an ice cube or freezer block on forearm skin for 10-15 minutes. The site should be examined 10-15 minutes after removal of the cold stimulus once the skin has warmed up (otherwise vasoconstriction will impair plasma extravasation).

INVESTIGATIONS
Routine investigations are not considered necessary in acute urticaria.1,2 For patients with CSU a differential full blood count and inflammatory markers (ESR or CRP)
Urticaria is characterised by transient wheals that consist of a swollen palpable centre often surrounded by an erythematous flare, associated with itching or, less commonly, a burning sensation. Individual wheals usually disappear within 1 to 24 hours leaving normal skin. Wheals may be accompanied by angioedema, a more deep-seated flesh-coloured or erythematous swelling of skin or mucous membrane, which may last longer than 24 hours.

Urticaria is classified as acute when it resolves within six weeks and chronic when its duration exceeds six weeks. Chronic urticaria is now sub-classified into chronic spontaneous urticaria (CSU) and chronic inducible urticaria (CIU). The prognosis for eventual recovery from spontaneous and inducible urticaria is excellent. However, the time course is unpredictable and may extend to years, often following a relapsing and remitting course.

Urticaria results from the release of inflammatory mediators from dermal mast cells, resulting in vasodilatation, plasma extravasation, recruitment of immunologically active cells and sensory nerve stimulation. The cause of urticaria cannot usually be precisely identified for most affected individuals. IgE-mediated food allergy is rarely the cause of CSU in patients with the daily appearance of urticarial lesions, although it should be considered in CSU patients with intermittent symptoms.

For patients with CSU a differential full blood count and inflammatory markers are all that are routinely recommended. It is also reasonable to test thyroid function and check for circulating thyroid autoantibodies as there is an association between CSU and thyroid autoimmunity.

For older patients with intermittent chronic urticaria and young children with acute urticaria, a food diary, investigation for circulating specific IgE to suspect foodstuffs and latex, and skin prick testing may be considered.

H1 antihistamine therapy is recommended as first-line symptomatic treatment for urticaria. It should be taken continuously rather than on demand, in the lowest effective dose. The timing of the antihistamine treatment should be adjusted to ensure maximum blood levels of the drug when urticaria is anticipated to be at its worst.2 Trials of at least two non-sedating H1 antihistamines should be offered as response and tolerance varies between individuals.2 Lack of response after two weeks to a second-generation H1 antihistamine in standard licensed dosage should prompt consideration of increasing the dose up to four-fold higher than the recommended dose, as second-line treatment, in otherwise healthy individuals. This is preferable to using several different H1 antihistamines over the course of a day. It is reasonable to consider (in addition to a second-generation antihistamine) a sedating H1 antihistamine such as chlorphenamine or hydroxyzine at night if sleep is disturbed.2 The addition of an H2 antihistamine, such as cimetidine, off licence may provide better control of urticaria in refractory cases.2 Urticaria remaining poorly controlled after a further one to four weeks may be explained by a relatively greater involvement of mast cell mediators other than histamine. A trial of the leukotriene antagonist montelukast can be added, off licence, to the high-dose H1 antihistamine regimen, as third-line therapy.2,3 Although the long-term use of oral glucocorticoids in urticaria is not recommended, a short course of prednisolone (up to seven days) for the treatment of acute exacerbations or to cover important events such as exams or a wedding, may be given.1 In individuals with a history of severe potentially life-threatening angioedema, an epinephrine autoinjection should be supplied for self-administration in an emergency, and the patient or carer carefully instructed in its use.

H1 antihistamine therapy. Omalizumab is a monoclonal antibody that selectively binds to human IgE, thereby lowering free IgE levels. Other immunosuppressant options (such as dapsone, sulfasalazine, methotrexate, mycophenolate mofetil, phototherapy, plasmapheresis, intravenous immunoglobulin and anti-TNF-alpha agents) have only a very low evidence base in urticaria, but may be useful in certain circumstances. Referral to a dietician should be considered for patients embarking on a low pseudoallergen diet.

CONCLUSION
Many of the recommendations relating to the basic treatment of urticaria involve the use of drugs off licence.2 The treatment aim in urticaria should be for complete symptom control as safely as possible2 in view of the potential for this condition to have a very significant adverse impact on quality of life.
